# Data Sources and Analysis for "How Deadly Were Gotham's Tenements? Infectious Disease in the 19th Century" Parts I and II 

Troy Tassier and Jason M. Barr

November 27, 2023

## I. Data Sources for Paris I and II

Data on mortality was obtained from the NBER Union Army Data - Historical Urban Ecological (HUE) Data at https://www.nber.org/research/data/union-army-data-hue. For post Part I, for each year in each ward, we collected data from 1868 to 1910 that contained deaths from contagious and other types of disease that were collected annually from the New York City Department of Health. The files were generally entitled, "Deaths from Zymotic \& Certain Other Preventable Diseases by Wards."

Death by Disease Count: To analyze contagious disease deaths we included total deaths from the following categories: Cholera, Cerebro-Spinal Meningitis, Diphtheria \& Croup, Typhoid, Typhus Fever, Malarial Fevers, Measles, Scarlet Fever, Small-Pox, Whooping Cough, Diarrheal Diseases, Tuberculous, and Pneumonia (over the years there were slight variations in categories, so we included counts of all contagious diseases for each year). We then added up all these deaths to get a total deaths from disease.

Population and Density: For each ward, population counts were given in the Dept. of Health files and were collected from state or federal censuses. For intermediate years, we interpolated the population by first estimating the average growth rate via: $r_{t}=\frac{\ln \text { Pop }_{t}-\ln \text { Pop }_{t-n}}{n}$, where $n$ is number of years between two censuses. Next for inter-census years, we estimated population values via:

$$
\text { Pop }_{t}=\text { Pop }_{t-1} e^{r_{t}}
$$

Land areas for each ward are given the HUE files each year. We used land area ca. 1900. Density was calculated as population per acre.

Furthermore, several years included personal property and real property values by the ward. Earlier years tended to contain personal property values while later years contained real property. For the analysis below we include the latest years for which data are available in all wards (1856 personal property, 1893 real property).

Historical Ecology: Data was collected from the Welikia Mannahatta Project maps, which estimate the location of various ecosystems, including the presence of wetlands, rivers and streams, lakes, and main tree types. The data was geocoded in the following way. If a Manhattan block contained one of these features, the feature was given a 1 for the block, and 0 otherwise. For example, if there were oak tulip trees the block the Oak Tulip variable for the block was assigned a one. Then for each block, we added up the number of blocks that had each feature and divided by the total number of blocks to get the percentage with the feature. The variables of
interest here were the percentage of blocks with a ward that had an oak tulip tree, and the percentage that were below sea level (indicating the presence of wetlands).

Demographics: Using data from the 1890 census we calculated for each ward the percentage of Russian or Polich people living in each ward from Vital Statistics of New York City and Brooklyn (1894).

Data on permits for water/ sewer and ventilation collected from HUE data set summaries of New York City Department of Health reports. Data on rear tenements and total tenements taken from HUE data set tenement house census reports.

Tenement Population Data: For 1870 and 1900 are part of the HUE data above in their respective years.

## II. Part I Data and Results

## 1. Descriptive Stats

Here are the ward-level descriptive stats for the per capita deaths by infectious disease from 1869 to 1910. In Equation (2) below, we removed the largest three, which were in around the $99.5^{\text {th }}$ percentile.

|  | Percentiles | Smallest |  |  |
| :---: | :---: | :---: | :---: | :---: |
| 1\% | . 00243 | . 0007042 |  |  |
| 5\% | . 0033766 | . 0019472 |  |  |
| 10\% | . 0038997 | . 0020411 | Obs | 659 |
| 25\% | . 0055212 | . 0021436 | Sum of wgt. | 659 |
| 50\% | . 0077923 |  | Mean | . 0096488 |
|  |  | Largest | Std. dev. | . 0057459 |
| 75\% | . 0130044 | . 0307152 |  |  |
| 90\% | . 0169765 | . 0315972 | Variance | . 000033 |
| 95\% | . 02155 | . 0342286 | Skewness | 1.352061 |
| 99\% | . 0297562 | . 0370832 | Kurtosis | 5.078971 |

## 2. Regressions

To compare death rates across wards, we first computed the death rate for each ward by calculating $D R=$ deaths from diseases/population. We then regressed $D R$ on ward and year dummies for the years we had data between 1866 and 1910. The omitted ward was 20 , which had a death rate very close to the city average. Note we excluded the two largest outlier values from the regression, given that the outliers seemed like possible errors (results in Column (2)). In the table, we can see that the ward dummy coefficients with and without the outliers are very close. Only Ward 12-the largest northern most ward-changes in any fashion.

For the map in Post I, we set coeff. values $\leq-0.00115$ as less than the average, $>0.0055$ above the average, and between $>-0.00115-\leq 0.0055$ as about average

Table I: Regression Results

## III. Part II Results

## 1. Anecdotal Evidence on Risk Differences Across Wards

## i. The History of Paradise Square: The Fall of Paradise

We can get a better sense of what the older tenements were like by considering the early history of one of New York City's most notorious tenement neighborhoods, Five Points, which sat in the $6^{\text {th }}$ Ward of Manhattan. Much of this neighborhood sat upon or in the vicinity of what was once Collect Pond. Collect Pond was a 48-acre body of fresh water fed by an underground spring. Until the early 1800s, it was a primary source of drinking water for lower Manhattan.

However, it came to be surrounded by slaughterhouses, tanneries, breweries, and other industries that required water or a place to dump debris and refuse. Over time the pond became polluted. Eventually, the stench and contamination led to the pond being backfilled and drained by a set of canals that led to the Hudson River. (The main canal is the present-day location of Canal Street in Manhattan.)

After the pond was filled, real estate developers took advantage of the new land atop Collect Pond to build a residential neighborhood which they named Paradise Square. Originally Paradise Square attracted the wealthy who were steadily settling farther and farther north on the island. However, the presence of the underground spring and the marshy land surrounding it led to the neighborhood being anything but a paradise. Continually, the soil and streets were soggy and wet.

Many of the newly built apartment dwellings and homes began to sink and to settle unevenly. The affluent people for whom Paradise was built began to leave as the neighborhood fell into disrepair. The owners then began to subdivide the now undesirable buildings, as well as the old factories and tanneries, into small rooms that were lent primarily to recent immigrants seeking the most inexpensive housing. Because many of the newly partitioned apartments and rooms were made by subdividing larger buildings, they often lacked ventilation and exterior sources of light. In addition, most lacked connections to sewers and some did not even have access to
outhouses. In this case, human waste was simply discarded into alleys or holes were dug into the soggy soil. It was within this unsanitary and unventilated building stock that many lived in the Five Points/ Sixth Ward tenements. The original tenement laws were written to improve these abhorrent living conditions.

## ii. Report of the Tenement House Department

Beginning with the Report of The Tenement House Department of the City of New York 1902/1903 areas of New York City were divided into tenement districts. All of Manhattan contained 11 tenement districts. Two of these are of interest to the present question. The area south of $14^{\text {th }}$ Street contained two districts, east and west. Unfortunately, these districts did not conform precisely to the ward boundaries of the city so we cannot match the data exactly to information about wards. But the report does provide information on the number of new tenements built throughout the city.

Between January 1902 and July 1903, the area south of $14^{\text {th }}$ Street on the east side of the city erected 260 "new law" tenement buildings while the west side erected only 57. Further, the total number of new tenements on the Lower East Side represented 45 percent of all new tenements in the entire city. This is a huge fraction of such a tiny portion of the city's land area. Additionally, one can see from a map provided within the report that most of the 260 new tenements were built in the safer wards. Subsequent years of the Tenement House Department Reports also list much larger shares of tenement construction on the east side of lower Manhattan than on the west.

| City Mean |  | 46.9454545 | 0.75849231 | 7.408181155 | 304\% | 226.78 | 44\% | 35\% | 428.2309243 | 3631.142091 | 67\% |
| City Median |  | 50.7 | 0.78588417 | 5.874136188 | 126\% | 165.07 | 45\% | 23\% | 82.28214394 | 947.716021 | 69\% |

This table shows that density, tenement percentage, and population growth, and wealth were unlikely to account for the infectious disease risk difference across wards. Lack of rear tenements, new construction, and access to running water and sewage likely explained a large fraction of the difference. The wards with Eastern Europeans likely had newer building stocks and those with higher relative social mobility than those who remained in Five Points, for example.

## 3. Regression Results

Here, we use the 22 ward fixed effects from the Regression Table I above, using Equation (2) (i.e., without extreme outliers). We regress the fixed effects on several ward characteristics, including the presence of oak tulip trees (which indicate land with good drainage), percentage of blocks below sea level, log of density, percentage of residents from Eastern Europe, percentage of rear tenements, $\log$ of the land area of the ward, the log of number of structures that applied for plumbing/ sanitation permits and the log of number of structures that applied for additional light or ventilation permits.

As the table below suggests, more rear tenements were associated with a higher death rate, while more access to plumbing was associated with a lower death rate. Oak Tulip trees and the Eastern European population appear to have had lower death rates, though statistical significance varies.

Given that there are only 22 observations, the results can best be interpreted as suggestive, rather than causal.
